## APPENDIX A

### **Methods used to calculate infiltrated volume**

Analysis of daily infiltrated volume by sector for the period of March 23 to April 2014 was performed to include deliveries from Morelos Dam because in April 13 deliveries from Km 27 began, the two events must be separated in order to do not incur on calculation errors accounting that sectors are delimited by the discharge measurements sites. Study area extension from Sector 2 to 5, because Sector 1 and Sector 6 to 9 had water in the river channel before the Pulse Flow event and there is no sufficient or none data for two of the three methods analyzed in this report.

The calculation of each sector daily infiltrated volume was performed by three methods: 1) Total measure volume in each sector less volumetric outputs of the system by direct evaporation and evapotranspiration, 2) Multiplying the daily flooded area by estimated infiltration rates obtained by Green and Ampt (1911) method, and 3) multiplying the daily flooded area by the average vertical flux obtained by the proposed method by Hatch et al., (2006).

For calculated by last two methods dairy inundated area of river channel by sector was used, this area was calculated with water elevation records from river stage data collected during the pulse flow, with daily registers a water elevation raster was generated and inundated daily surface was generated subtracting the resulted raster to the LiDAR elevation raster. Inundated area was obtained inside the channel, meanders and terraces; not connected areas were deleted to avoid over estimation of inundation.

Channel area was determinate with a surrounding polygon with which the inundated area of the channel was discretized. Assumptions in the calculus of inundated area were: 1) a constant water elevation slope between river stages, 2) water elevation maintains the same for river channel, terraces and meanders, 3) not connected inundation areas were eliminated assuming this happen in the flow event, and 4) to create inundated surface decimal data were rounded to an integer value.

Infiltrated volumes in the river channel were obtained using infiltration rates resulting from Green and Ampt (1991) and Hatch et al., (2006) methods, because we have data only in the dry river channel infiltrated volume by using this two methods accounts only losses from the river channel the rest of the infiltrated volume in each sector is assumed to be losses in meanders and terraces.

Analysis of infiltrated volume in Sector 2 to 5 would provide detailed information about the infiltration process along the dry reach.

#### **Method 1. Daily discharge measurements.**

Daily discharge measurements were used to calculate total volume enter to each sectors (figure 1), the total infiltrated volume during the analysis period was obtained subtracting losses caused by direct evaporation and evapotranspiration from the total volume lost within the sector (formula 1).

**Formula 1**

$$V_{total. \text{ Inf.}} = (Vin - Vout) - VET - VEV$$

Donde:

$V_{total. \text{ Inf.}}$ = Total infiltrated volume by sector ( $\text{m}^3$ )

$Vin$ = Volume entering to the sector ( $\text{m}^3$ )

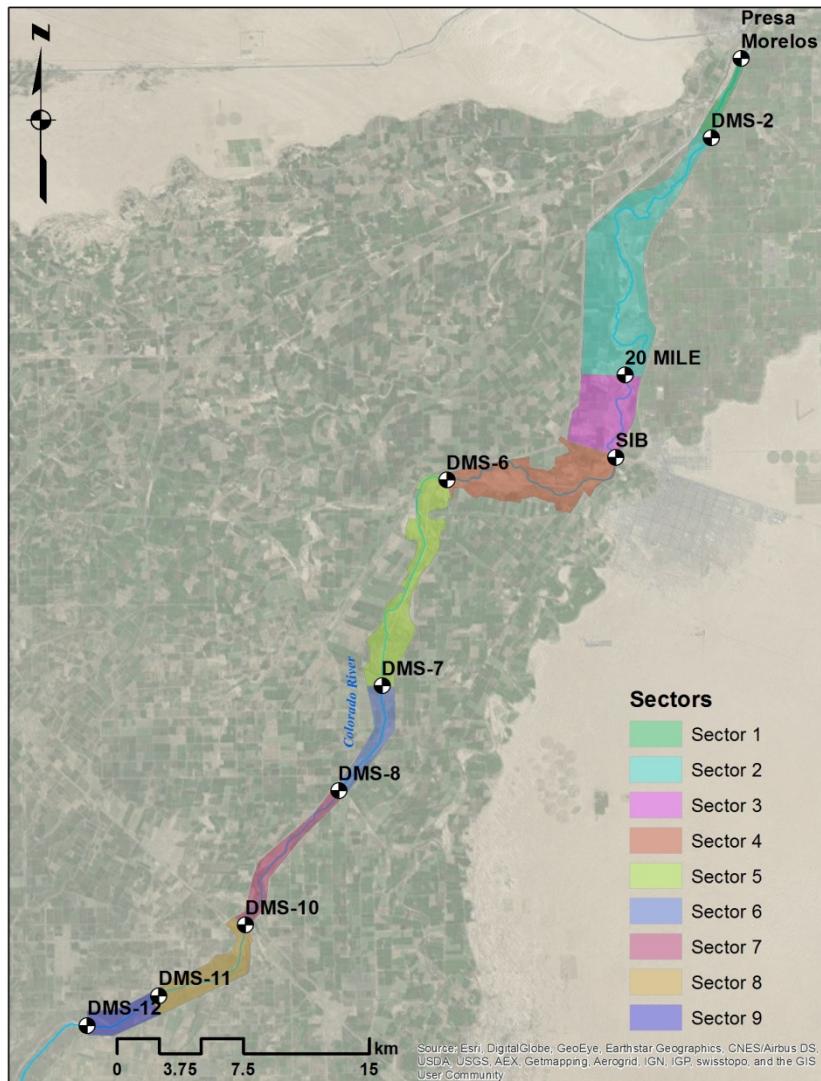

$Vout$ = Volume out of the sector ( $\text{m}^3$ )

$VET$ = Evapotranspirated volume

$VEV$ = Direct evaporation volume

Assumptions and limitations:

1. Discharge remains constant all day
2. Evapotranspiration and direct evaporation are considered maximum values because of the methods used.
3. Equipment and measurements precisions in discharge measurements.

**Figure 1.** Defined sector by Discharge measurements sites (DMS).

**Method 2. Infiltrated volume calculated using infiltration rates resulting from Green and Ampt (1911) method.**

Green and Ampt (1911) proposed an infiltration model for soils with homogeneous texture and uniform initial moisture content assuming a water content profile of piston type with a well-defined wetting front, known as Green-Ampt model. This model is based on the assumption of existence of an impregnation front with a constant potential while the wetting zone is impregnated uniformly with a constant hydraulic conductivity, form expressed mathematically:

**Formula 2**

$$F_{(t)} = K_t + \psi \Delta \theta \ln \left( 1 + \frac{F_{(t)}}{\psi \Delta \theta} \right)$$

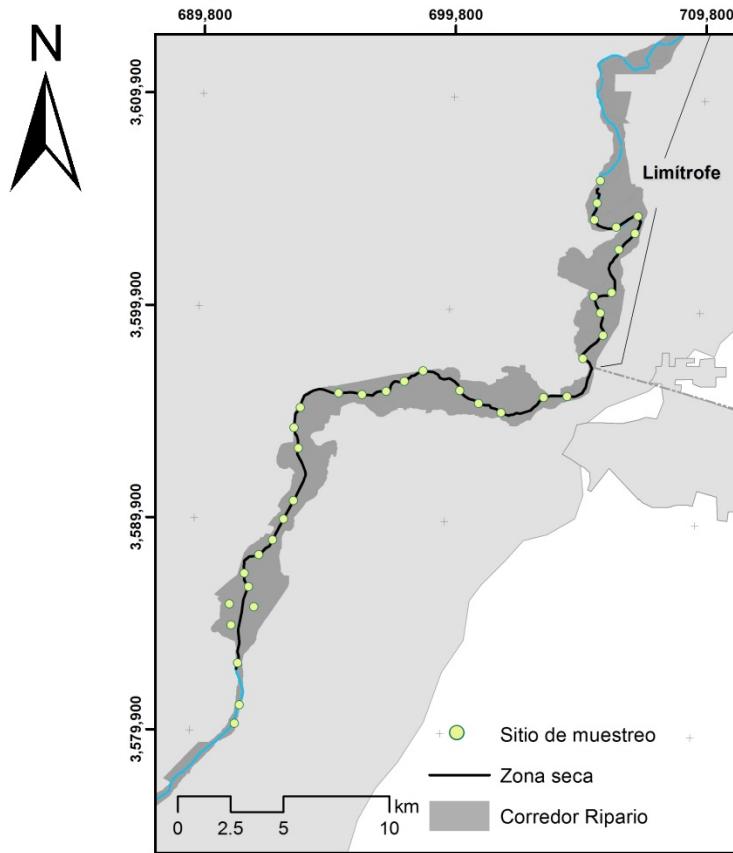

Where  $F_{(t)}$  accumulated infiltration,  $K$  (hydraulic conductivity, cm/h),  $t$  (time, h),  $\psi$  (potential wetting front suction, cm) y  $\Delta\theta$  (moisture content change, %). To obtain the value of  $F_{(t)}$  a test value is substituted  $F_{(t)}$ , in the right part of the equation. Obtained  $F_{(t)}$  value is substituted again in  $F_{(t)}$  in the left part to obtain a new value  $F_{(t)}$ . The processes is repeated until  $F_{(t)}$  values converges to a constant.

With the purpose to apply this method, sediment samples were taken (figure 1) along the dry river channel, sediment analyses were performed according to ASTM 2007 and 1995 ((Alarcón-Gómez, 2015) to obtain sediment physical properties and grain size.

From sediment properties with the Green-Ampt method punctual infiltration rates were obtain within the river channel. Infiltrated volumes were determinate multiplying infiltration rates to inundated areas in the river channel, a value of infiltration rate for each sector remain constant during the analysis period.

Assumptions and limitations:

1. Infiltration rates remain constant and are a single value for each sector for all the analysis period.
2. It doesn't quantify losses by direct evaporation or evapotranspiration directly are assuming to be included in the inundation area indirectly.
3. Uniform initial moisture and constant hydraulic conductivity.
4. Humedad inicial uniforme y conductividad hidráulica constante

**Figure 2.** Sitios de recolección de muestras de sedimento del lecho del río (Rodríguez-Burgueño et al., 2015).

#### **Method 2. Infiltrated volume calculated by vertical fluxes obtained with proposed method by Hatch et al., (2006).**

The use of heat as a tracer to determine fluid flux between groundwater and surface water has become a popular technique, with interest demonstrated through recent reviews by Anderson (2005), Constantz (2008), and Rau et al. (2014), and over 100 citations for each of the Stallman (1965), Hatch et al. (2006), and Keery et al. (2007) papers that outline methods to estimate water flow from temperature time series data (Irvine et al., 2014).

Analysis of temperature time series obtained each 2 minutes in the hydrologic monitoring of the pulse flow were performed with proposed methods by Hatch et al., (2006), Kerry et al., (2007), McCallum et al. (2012) y Luce et al., (2013); in VFLUX program (Gordon et al., 2012; Irvine et al., 2014). These methods are based on the analytical solution of the equation (formula 3) of heat transport proposed by Stallman (1955), using thermal properties of sediment and water. Solutions proposed in the methods consider information of the amplitude and/or phase angle changes in the diurnal signal between two temperature series at different depth of the riverbed in the main channel (figure 3), to estimate the vertical flow through the sediment column analyzed. Methods assume that thermal properties of sediment and water remain constant during all analyzed period of time.

**Formula 3**

$$\rho_m c_m \frac{\partial T}{\partial t} = \lambda_m \frac{\partial^2 T}{\partial z^2} - q \rho_w c_w \frac{\partial T}{\partial z},$$

Where:

m= denotes sediment-water system (matrix)

w= water, moving portion of the system

T= Temperature (°C)

t= time (s)

z=depth from riverbed (m)

q= Darcian flow velocity or filtration flow ( $\text{ms}^{-1}$ )

$\rho$ = density of the medium (water or matrix;  $\text{kg m}^{-3}$ )

c= specific heat of the medium (water or matrix;  $\text{J kg}^{-1} \text{°C}^{-1}$ )

$\lambda_m$ = Thermal conductivity of sediment-water matrix ( $\text{W m}^{-1} \text{°C}^{-1}$ )

Estimation of vertical flux was calculated using VFLUX (Gordon et al., 2012; Irvine et al., 2014), in which first the movement of the daily heat wave (phase) and the ratio of the amplitude changes of the temperature signals are analyzed at each depth. VFLUX is a program in MATLAB language that synchronizes and resamples the temperature data obtained by sensors on the vertical profile. Isolates diurnal signal of each time series and extracts the amplitude and phase using the method of Dynamic Harmonic Regression (DHR, Young et al., 1999). With both parameters calculated vertical flows through the formulation of the solution presented by each method, which estimates the flow velocity in one dimension (vertical).

Thermal properties of the sediment and water were considered constant during the analysis period, sediment thermal properties were calculated using the results obtained in sediment analysis by Alarcón-Gómez (2015) using average porosity of the sediment (0.464) the bulk density was obtain (1.37) according to Wilson et al., (1994), using this value according to Lapham (1989) the thermal conductivity (0.00275) and volumetric heat capacity of the sediment (0.684375) were obtained, volumetric heat capacity of water was obtained from values reported on USGS (2003).

Vertical fluxes for each pair of sensor were calculated each two hours, fourth methods were analyzed using VFLUX; a daily average of the results for each site was performed to analyzed daily vertical infiltration rates over the period, from which was determinate that the method proposed by Hatch et al., (2006) represent results without anomalies. According to recent studies (Lautz, 2010; Roshan et al., 2012; Cuthbert y Mackay, 2013 in Irvine et al., 2014), is demonstrated that methods proposed by Hatch et al., (2006) work best for downwelling flow than for upwelling, in general, the equations using the ratio of the amplitudes of temperature signals are less prone to mistakes in equations than using phase shift between the time series (Irvine et al., 2014).

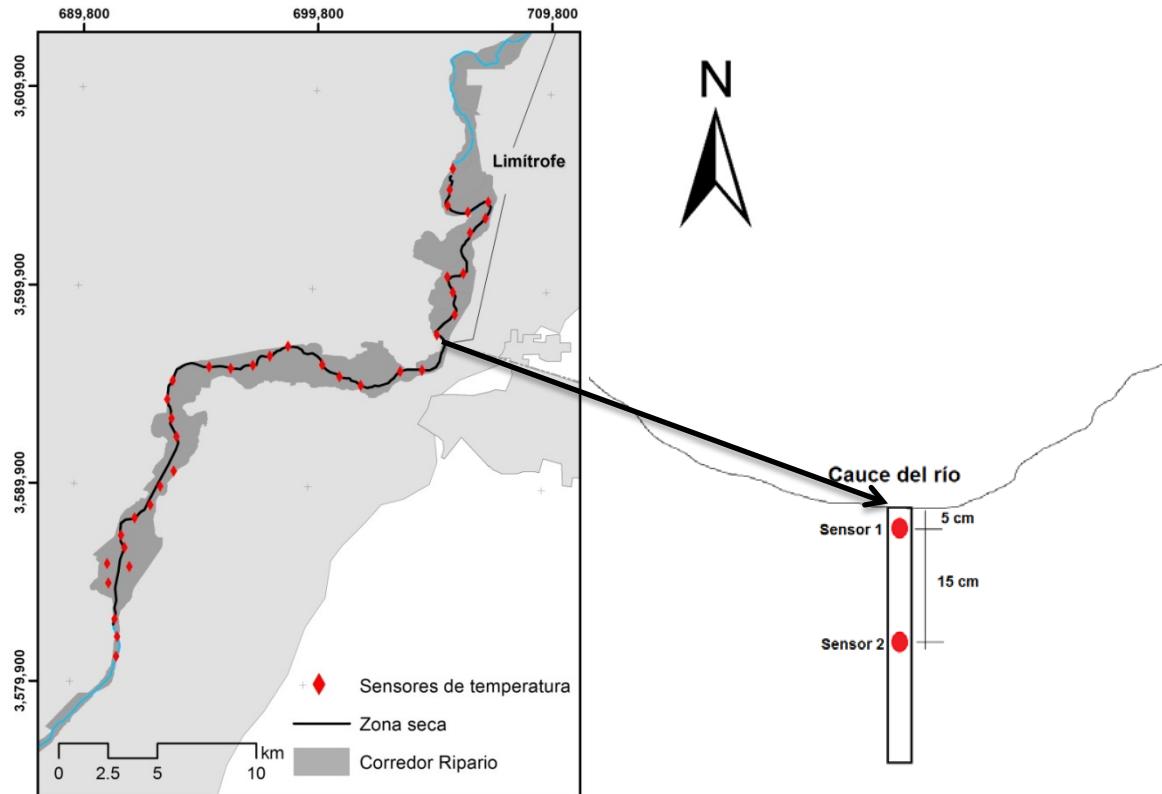

Figure 3. Location of temperature loggers and diagram of installation in the (Rodríguez-Burgueño, et al., 2015)

Results of daily average values of vertical infiltration flux proceeded to calculate the volume infiltrated by sector, they were required to sever the areas of sectors according to the location of temperature sensors analyzed, an analysis of the affected area by each sensor was conducted considering the channel sinuosity, width and shape to unify criteria (Figure 3).

In sector 2, in a larger polygon area no information is available about the infiltration rate, because this area had water before the pulse flow, for which the average value of the calculated data of the pair of sensors T2 was used (Figure 4). Next the percentage area of incidence of each site to multiply by the daily flood areas of each sector and to obtain the percentage of flooded area within the channel that corresponds to each sensor is calculated.

Obtained incidence area proceeded to calculate infiltrated volumes by the river channel at each site, multiplying the area of incidence of each sensor by average daily infiltration rates obtained by Hatch et al., (2006) method. To quantify the total infiltrated volume by the river channel in each sector each volume obtained inside the sector was summed.

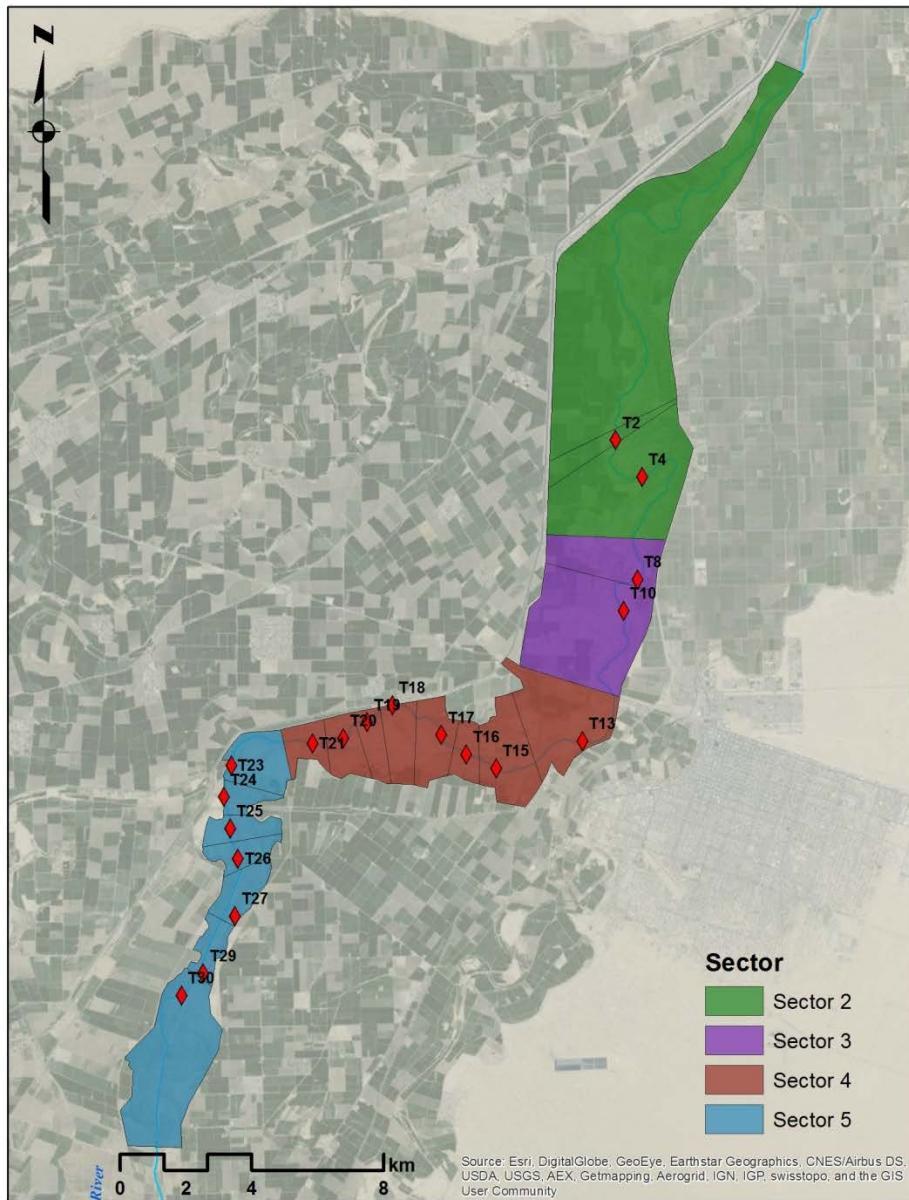

Figure 4. Sector segmentations according to analyzed temperature logger location.

Assumptions and limitations:

(Irvine et al., 2014)

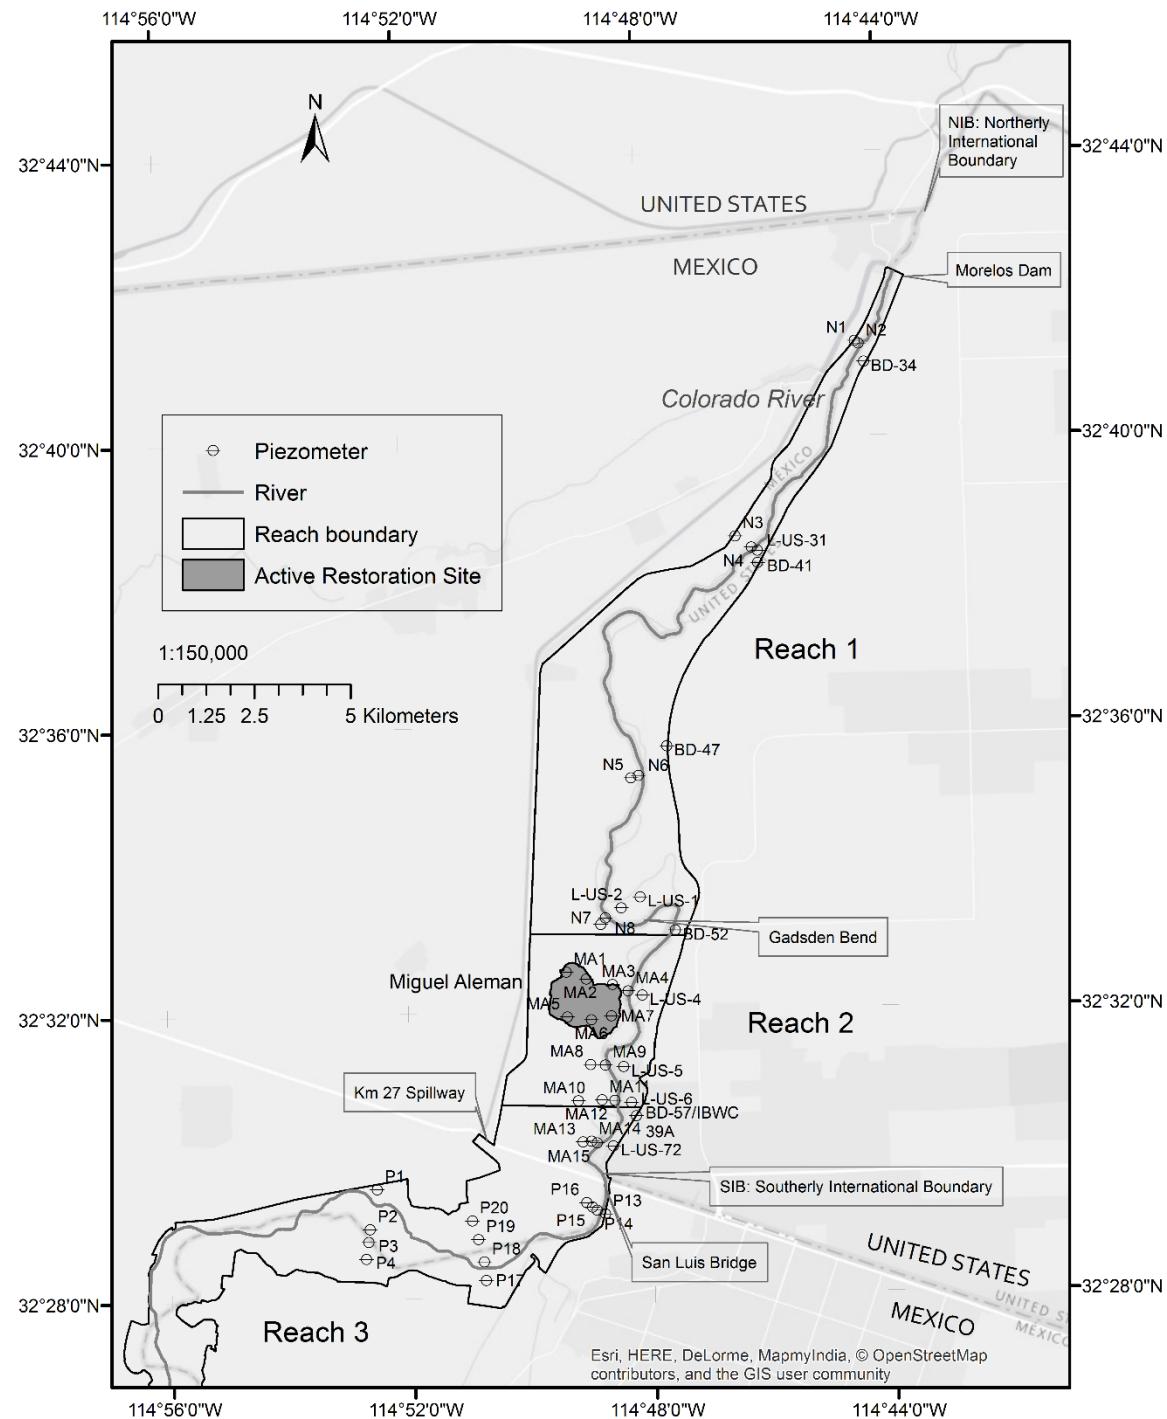

1. Water flow is vertical and one-dimensional,
2. Temperature signal at the upper boundary is sinusoidal
3. There is no thermal gradient with depth in the streambed
4. There is thermal equilibrium between the pore water and the streambed materials
5. Streambed thermal and hydraulic properties are homogeneous.
6. Scour and sediment deposition are a very important process that may interfere with results.

## Appendix E

### Minute 319 Vegetation Monitoring Methods and Results

#### I. Vegetation Monitoring

##### 1. River Corridor Seedling Transect Monitoring:

We assessed seed rain of the principal woody plants, vegetation change (including seedling recruitment), topographic change, and sediment texture and conductivity along 21 transects in Reaches 1 through upper Reach 5, spanning river kilometers 1-93 (miles 1-57.3). Transect length varied depending on channel and floodplain morphology, ranging from 60-417 m (197 -1,368 ft). In 2014, sampling occurred in early March, before the beginning of the pulse flow, in mid-May, approximately four weeks after the cessation of flow releases from Morelos Dam, and again in October, at the end of the growing season. In 2015, sampling occurred in June and October.

Seedling transects were oriented perpendicular to the direction of flow, crossed the primary natural flow channels, and extended above estimates of the highest stage associated with the flood pulse. In some places, areas outside of our initial (March) transect end points were inundated, in which case we extended the transects during our May field campaign. In one case, we re-located a transect upstream of its March location due to extensive human foot traffic in the original transect location. To enable linking vegetation responses to pulse flow hydrology, we located transects to coincide with groundwater and either surface water discharge or stage monitoring sites (see Fig. A-1).

Monitoring of seed rain occurred approximately every two weeks between early March and mid-June. Along each transect, seed rain was quantified by counting seeds on one or two seed traps located just above the expected maximum inundation point at the start of each transect. Traps consisted of a 0.6 m x 0.6 m (2 ft x 2 ft) plywood board coated with Tree Tanglefoot (Tanglefoot®, Contech Enterprises, Inc., Grand Rapids, Michigan) insect trapping material. Seeds that landed on the board were counted and identified to species (*Populus fremontii* – cottonwood; *Salix gooddingii* – willow; *Salix exigua* – sandbar willow; *Tamarix* spp. – saltcedar, and *Baccharis* spp. – seepwillow, Emory's baccharis). Following each sampling event, seeds and Tanglefoot were scraped from the plywood board and a new coat of Tanglefoot was applied. For each sampling date, we calculated the total number of seeds trapped on the board, per m<sup>2</sup>, by species. In addition, within an approximately 200m (656 ft) wide belt centered on each transect, we estimated how many individuals of each of the woody taxa above were dispersing seed, and the relative abundance of seed dispersal (none, light, moderate, heavy).

To assess vegetation change and seedling recruitment, we noted cover of live vascular plants, litter, and water that intersected our transect line using a line-intercept survey method. For the purposes of this report, we refer to plants that germinated following the pulse flow release as seedlings. We strung a measuring tape along the transect line and recorded the length that each cover type intersected the line. For patches containing new seedlings, which were only present in May, we noted the intercept lengths within a one-meter (3.3 ft) wide belt. We summarize these data by calculating the proportion of each transect intersected by the different cover types, and the proportion of bare ground before and after the pulse flow. We obtained an estimate of new seedling densities observed in May by counting woody seedlings, by species, in one-hundred and twenty-four, 0.25 m<sup>2</sup> (2.69 ft<sup>2</sup>) plots randomly placed within seedling patches.

In October 2014, we added permanent plots along transects containing first year woody riparian seedlings in order to assess seedling growth and survival over time. We measured length of seedlings zones within the one-meter belt and within a 20 m belt upstream of seedling transects. We established plots of 40 m<sup>2</sup> (generally 4 x 10 m, upstream) in the seedling zones and counted the number of seedlings of woody species in the plot, measured heights of ten randomly selected individuals and covers of all species (seedlings, adult individuals, non-perennial species) present in the plot. When the plot had a

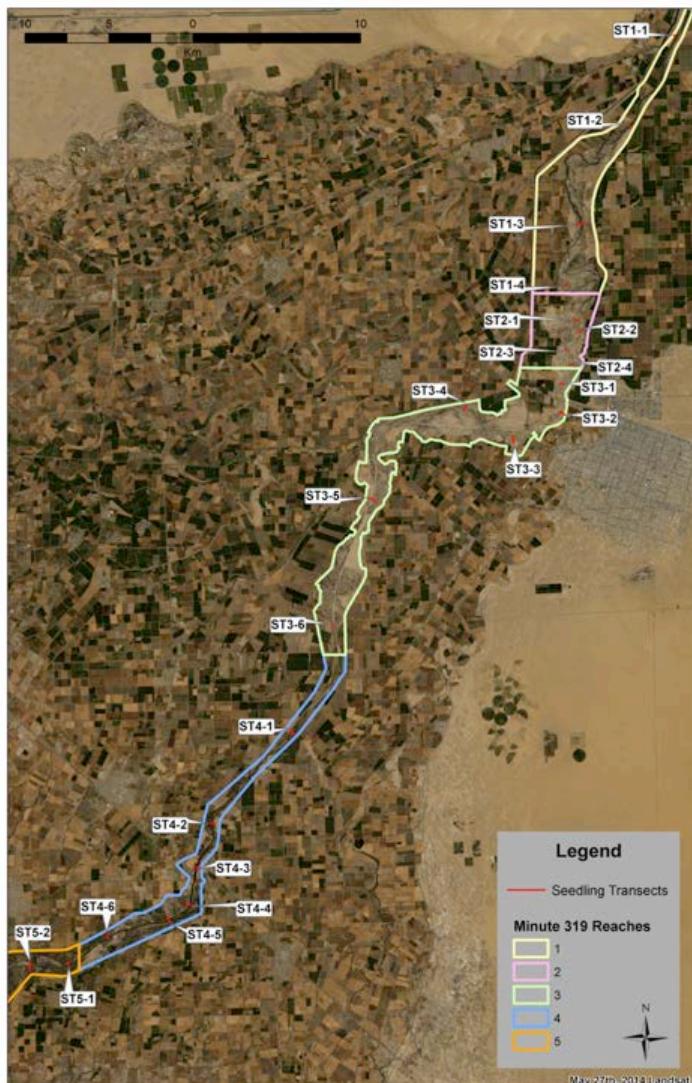

higher density of seedlings we used five subplots of 1 m<sup>2</sup> placed on the corners and middle of the plot to average seedlings density and species cover. We averaged seedlings density from the plots by target species on each transect.

Results are averaged by river reaches 1-5. Seedling density (individuals per 1 m<sup>2</sup>; per 10.8 ft<sup>2</sup>) of each species was calculated from 40m<sup>2</sup> (430.6 ft<sup>2</sup>) seedling plot count data in October 2014 and 2015 (Tables A-1 and A-2). Frequency of species presence was also determined in October 2014 and 2015 by calculating the percentage of transects per reach in which a species was present (within the 1-meter (3.3-ft) belt) (e.g. if willow was present in 4 out 5 transects, frequency would be 80%).

Along each transect, we also collected physical environmental data, to be used in future analyses relating vegetation pattern to processes associated with the pulse flow. We collected soil samples during March, May, and October 2014 surveys. In March and May one sample (10 cm depth) was collected from each primary geomorphic surface present along the transect. Each sample was a composite of four subsamples and were analyzed for grain size distribution and electrical conductivity (a proxy for salinity). The number of samples varied between surveys due to the difference in transect lengths and locations following the pulse flow release. In addition to this set of samples we included 33 soil surface samples from the limitrophe taken in March before the pulse flow and 27 samples taken in April after the pulse flow. Samples were taken from twenty-three channel cross-sections established in Reach 1, Reach 2 and one transect from Reach 3 on surfaces of different elevations inside the zone most likely to be inundated.

In October 2014, we took 32 soil samples from the seedling plots established along transects. We sampled the corners and middle point of each 40m<sup>2</sup> plot to obtain a composite sample per plot. Maximum survivable soil salinity was based on previous studies, and actual soil salinity was determined per transect and sampling period.

Finally, we surveyed the topography of each transect in both March and May, using a high resolution, RTK-GPS system. Topographic surveys also captured soil sample locations, permanent rebar placed along each transect to enable local registration and transect relocation, and nearby piezometers. Topographic surveys will allow us to relate the local elevation of seedling patches to adjacent river stage and depth to alluvial groundwater. LiDAR-based digital elevation maps will also be used.

**Figure A-1.** Seedling transects locations in Reaches 1-5 of the Colorado River in Mexico.

## 2. Sonoran Institute Laguna Grande Monitoring:

The following section is on monitoring conducted in the Laguna Grande Restoration Area, which is made up of three land concession polygons (see Fig. A-2).

**Figure A-2.** The Laguna Grande Restoration Area is composed of three concession polygons: CILA, Cori, and Laguna Larga.

### 2a. Laguna Grande Transect Vegetation Monitoring:

The objective for monitoring meander belt transects was to determine if cottonwood-willow establishment was achieved by the pulse flow alone (passive restoration), and/or establishment was enhanced by vegetation clearing before the pulse flow (assisted passive restoration). To achieve these objectives, Sonoran Institute determined the presence and density of native trees and shrubs established in:

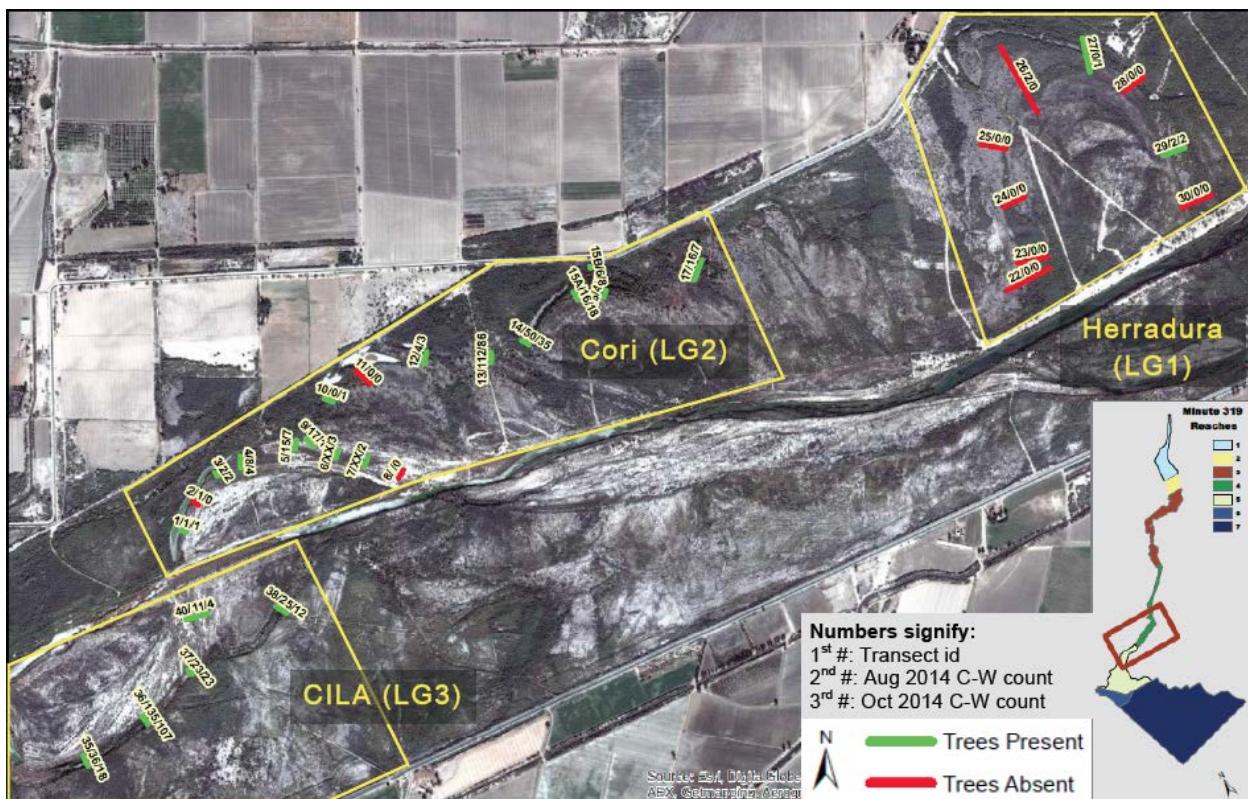

1. Un-cleared areas that were not inundated during the pulse flow (control).
2. Un-cleared areas that were inundated during the pulse flow (passive).
3. Cleared areas that were inundated during the pulse flow (assisted passive).
4. Cleared areas that were not inundated during the pulse flow (cleared).

To detect establishment in control areas, we monitored transects in Laguna Grande in areas that were not inundated or cleared (populated by saltcedar and arrowweed). To detect establishment in passive areas, we monitored transects along adjacent a meander at Laguna Grande that was inundated during the pulse flow, but was not cleared beforehand. To determine if clearing and inundation increased passive establishment, we monitored transects in assisted passive areas within the Laguna Grande restoration polygons – areas that were cleared before the pulse flow and experienced inundation for at least some

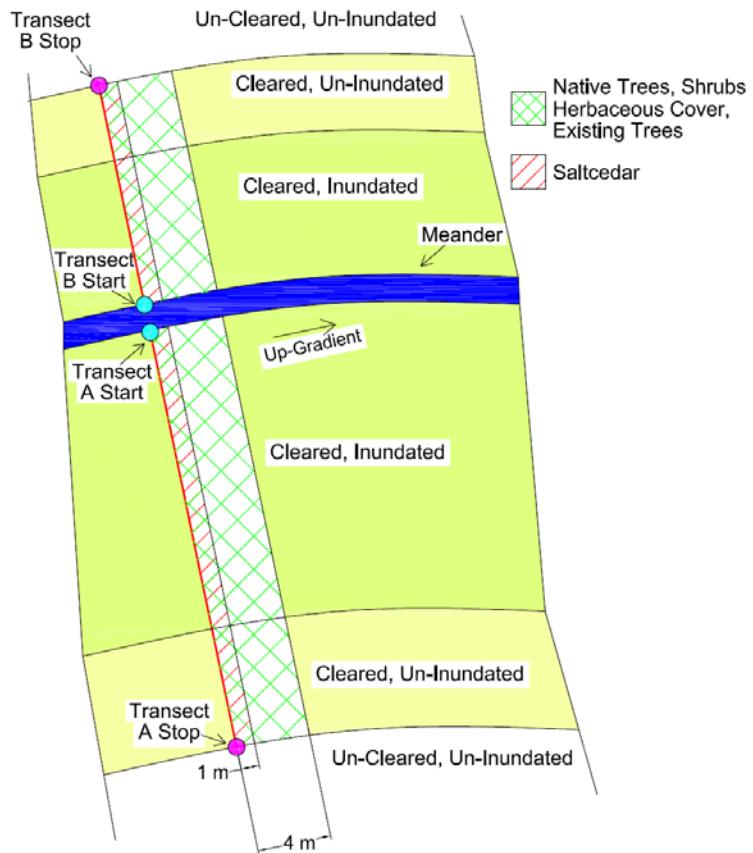

portion of the pulse flow delivery. To detect establishment in cleared areas, we surveyed cleared areas in Laguna Cori and CILA that were anticipated to be inundated but did not actually experience surface flows.

Management and inundation categories were delineated using GIS (see Fig. A-3). Modeling projections for the Minute 319 pulse flow were used to determine areas likely to be inundated. For “control” monitoring, four transects were placed in reference areas in the Laguna Cori polygon. For “passive” monitoring, and four transects were placed in the Laguna Grande restoration area but outside of the concession polygons. For “assisted passive” monitoring, 35 transects were placed approximately every 400 m perpendicular to the bottom of constructed and existing meanders. For “cleared” area monitoring, we planned to extend the “assisted passive” transects to the edge of clearing. However, no establishment was observed in areas far from inundation areas, and transects were instead ended at the end of the recruitment zone.

Start and end points for transects were adjusted based on field conditions. Belts were started at the water edge where surface water remained, or at the bottom of the channel if surface water was no longer present, and extended perpendicular from the channels until they exited the zone of inundation. When both sides of the meander were similarly prepared, an “A” and “B” side was monitored. When only one side of the meander had been cleared, only that side was monitored. For each belt transect, we monitored the number, length interval, and cover of existing and seedling trees and shrubs, and length interval and cover of herbaceous vegetation. The monitoring schematic is shown in Figure A-4. A pilot monitoring effort was completed in August 2014 to confirm the ideal belt transect width for assisted passive areas. In October 2014, a full survey was completed; all assisted passive, cleared, and control transects were surveyed. Transects were surveyed again in May and October 2015.

**Figure A-3.** Laguna Grande transect locations (green and red lines) within the three restoration sites: Herradura (LG1), Cori (LG2), and CILA (LG3). Green lines represent transects where native trees were present in 2014, while red lines represent transects where native trees were absent in 2014.

**Figure A-4.** Schematic for passive vegetation establishment monitoring at Laguna Grande

Density estimates of plant species along the Laguna Grande transects were not directly comparable to density calculated for seedling plots in the reaches due to differences in scale and monitoring methods. Differences include methods used to determine placement, size, and orientation of the long-term monitoring plots. For the Laguna Grande transects, we calculated density of all species in 4x5 meter sections along the transect where any seedling was present (Tables A-3 and A-4). The comparison between Laguna Grande transect density and river corridor seedling transect density likely underestimates density of plants in the Laguna Grande area. Frequency however, is a direct comparison the prepared and the unprepared sites.

Although baseline vegetation cover data was not collected in March 2014 along Laguna Grande transects, existing vegetative cover was recorded during October 2014 and May 2015 transect surveys. Percent bare soil was calculated by subtracting the visually estimated vegetation cover (excluding new seedling establishment) from 100. Surface flow volumes in Laguna Grande were not great enough to cause vegetation scour or sediment erosion and deposition; thus, we assume that environmental flows did not create new bare surfaces and that existing vegetation and bare soil cover in May 2015 was approximately representative of cover in March 2014.

## 2b. Vegetation Monitoring in Planted, Irrigated Restoration Areas:

For the first two growing seasons after planting, restored areas were divided into monitoring sections based on land preparation and species planting layout. Within sections, rows of vegetation were numbered, and a subset was randomly selected for monitoring. Within each selected row, live and dead

trees were counted. These numbers were used to estimate tree density and survival rate for each section. Four trees in the selected row were randomly selected and measured for height and diameter at breast height (dbh). Tree condition was recorded into classes as follows:

- Good condition: Trees that appear to be healthy with green leaves and little to no leaf discoloration or pest infestation.
- Poor condition: Trees that have a majority of brown and/or discolored leaves, or have high level of pest infestation, and appear to be dying.
- Dead.

This monitoring was conducted two months and four months after planting (first year vegetation), and twice in 2015 (April and October) for second-year planting areas. For 2014, 25 sections were monitored using these methods.

## **2c. Laguna Grande Soils Monitoring:**

Soil salinity monitoring was implemented in cleared areas within Laguna Cori during 2014 to determine pre (March 2014) and post-pulse (October 2014) flow salinity along historic channel meanders. An EM38 sensor (Geonics Limited, Mississauga, Ontario, Canada) was used to determine bulk electrical conductivity following methods from the US Salinity Laboratory (Lesch et al. 2000). A transect monitoring design was completed, whereby one transect was monitored perpendicular to meanders approximately every 50 m (estimated roughly by pacing). Along each transect, a reading was obtained every 10 to 15 m. At each point, a horizontal and vertical reading was collected. Actual point locations were recorded using a handheld GPS unit.

The ESAP program (US Department of Agriculture, Agricultural Research Service, Riverside, California, USA) was used to select sample locations for calibration of bulk electrical conductivity readings. Selected locations were sampled on 1-foot (30 cm) intervals and laboratory tested for soil texture, saturated paste extract (SPE) electrical conductivity (EC), and moisture content. Laboratory results were used to provide a predictive equation to estimate soil EC from EM38 horizontal and vertical readings at all monitoring points. ESAP is used to optimize sampling locations for each monitoring even, so the same locations were not laboratory-tested for both events.

The results were interpolated using ArcGIS to show the spatial distribution of pre- and post-pulse flow soil salinity across Laguna Cori. Interpolation grid cells values were used to estimate changes in 0-4 foot (0-1.2 meter) and 3-4 foot (0.9-1.2 meter) SPE EC between sampling dates. Cumulative probability density functions were used to determine the number of grid cells that fell below SPE EC tolerance thresholds for native species.

## II. Vegetation Monitoring Results (Additional Tables)

The following key plant taxa are referred to in the tables below:

- Fremont cottonwood (*Populus fremontii*; species code: POFR);
- Goodding's willow (*Salix gooddingii*; SAGO);
- Seep-willow and Emory's baccharis (*Baccharis* species; BASP);
- Tamarisk (*Tamarix* species; TASp)

# Appendix F. Pulse Flow Repeat Photographs

## About these photographs

This collection of photographs is part of an effort to monitor effects of the Colorado River “pulse flow” made possible by the Minute 319 agreement between Mexico and the United States. They are intended to show conditions before, during, and after the pulse flow by repeating the exact location and direction of each image.

These photographs were taken by staff of The Nature Conservancy, supported by a grant from the Terra Foundation. They may be used, with attribution, for scientific or other non-commercial purposes. Please provide credit to:

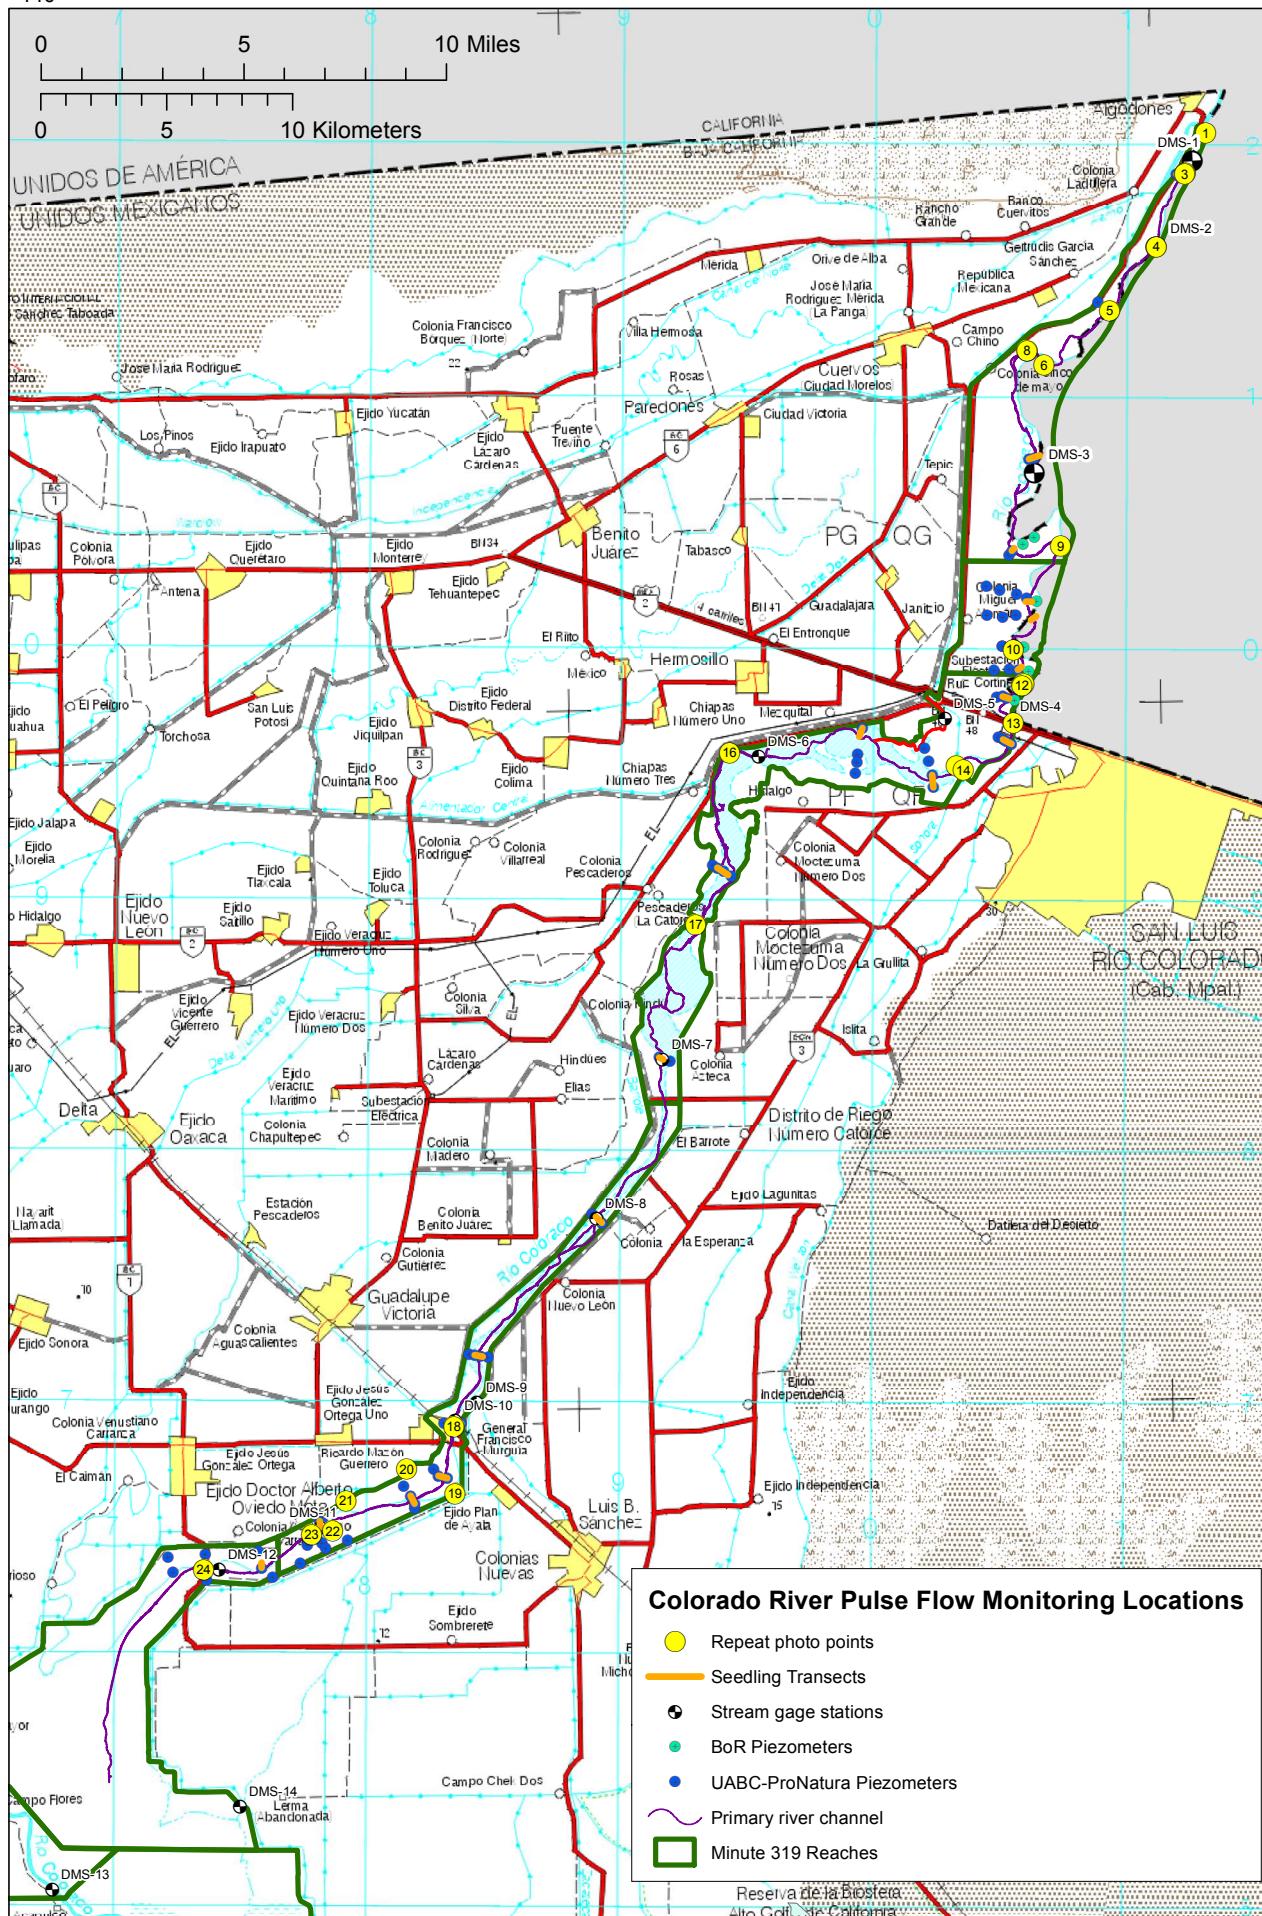

Dale Turner / The Nature Conservancy.

For further information about these photographs, contact:

Dale Turner  
[dturner@tnc.org](mailto:dturner@tnc.org)  
520-545-0182

Photographs were taken at fixed points, as shown on the map included here. The number of photos at a point ranged from one to three, depending on site conditions. Detailed data were collected for each photo, including locality coordinates, azimuth for center of view, and vertical tilt.

The original set of photographs was taken during March 18-21, 2014, the week prior to beginning of the pulse flow. The second set of photographs was intended to capture the peak flow, and was taken between March 27 and April 10. The third set was taken six months after the peak flow, September 27-30, 2014.
